Abstract

Despite the advances in biochemical methods and imaging techniques, Cushing’s syndrome (CS) related to ectopic adrenocorticotropic hormone (ACTH) secretion continues to pose diagnostic and therapeutic challenges to the clinician. The work up involves establishment of endogenous Cushing’s syndrome, diagnosis of ACTH dependency, localization of the source of ACTH secretion and rapid biochemical control of hypercortisolaemia. The diagnostic pathway is made difficult by recurrent sepsis, relative hypoadrenalism, drug side effects as well as unmasked incidental lesions.

We report a patient presenting with Cushing’s syndrome associated with ectopic ACTH secretion from a bronchial carcinoid whose management presented multiple diagnostic and therapeutic challenges.

Key words: Cushing’s syndrome, ectopic adrenocorticotrophic hormone, hypercortisolaemia, hypoadrenalism, incidental lesion, small cell carcinoma of lung.

Introduction

The syndrome of ectopic a ACTH secretion is one of the greatest diagnostic challenges in clinical medicine. The first association between cancer and CS was first reported in a patient in 1928 (1). However, it was only in the 1960s that ACTH production was demonstrated in tumours other than pituitary tumours (2). Following this, many malignancies other than small cell carcinoma of the lung (SCCL) were recognized to be causative for CS and in several large series, ectopic ACTH secretion has shown to account for approximately 10% of Cushing’s syndrome (3). The causative malignancies include carcinoid tumours of the lungs, thymus and gastrointestinal tract, islet cell tumours, phaeochromocytomas and medullary thyroid carcinomas (4).

The syndrome requires a complete workup that includes the establishment of endogenous CS, diagnosis of ACTH dependency, localization of the source of ACTH secretion and rapid biochemical control of hypercortisolaemia. The effects of severe hypercortisolaemia make the diagnostic pathway difficult. Here, we describe a patient with ectopic ACTH from a bronchial carcinoid tumour highlighting the unusual presentation and difficulties in management.

Case report

A 50-year-old police woman presented to the medical casualty department with acutely worsening shortness of breath, chills, rigors and general deterioration. She admitted that she was having a 12 month history of facial swelling, weight gain, hair loss, fatigue, dyspnea with poor effort tolerance, depression and generalized ill health. She had also developed diabetes mellitus and hypertension 1 year prior to presentation with no family history of the same and had poor control despite being on treatment. She denied any history of taking exogenous steroids or herbal medicine.

On examination, she was noted to be extremely breathless, pigmented, hypertensive and centrally obese. She had a clinically Cushingoid appearance with central obesity, proximal myopathy, easy bruising, facial puffiness and fat deposition in the dorso-cervical region. She had purple stria over her flanks and thighs as well as facial acne and hyperpigmentation of her extensor surfaces on her upper and lower limbs (figure 1). Thyroid examination was normal.

Preliminary investigations revealed that she was hyperglycaemic and hypokalaemic (potassium 1.7

Although her inflammatory markers and white cell counts (WCC) were not suggestive of an infection, chest X-ray suggested a bilateral pneumonic state and blood cultures confirmed a growth of *Staphylococcus aureas* and she was treated for staphylococcal sepsis and pneumonia with intravenous antibiotics.

She underwent a bilateral IPSS without corticotrophin releasing hormone (CRH) stimulation. The results of the sampling clearly demonstrated that the source of ACTH was unlikely to be the pituitary as the ratio between central to peripheral ACTH levels was 1.02.

Her clinical status was again compromised following the procedure where she developed a urinary tract infection and an abscess at the femoral puncture site. Her condition got progressed to septic shock and was resuscitated with fluids, inotropes and hydrocortisone therapy.

In the meantime, she had a CT scan of the chest, which revealed bilateral diffuse cavitatory lesions with patchy consolidation (figure 2). Interestingly, a single solid lesion in the right lower lobe was reported as a “nodule, which may represent metastatic deposit” and the radiology team suggested a CT guided biopsy. Even after this procedure, the patient became extremely breathless with type 1 respiratory failure. The CT findings were suggestive of early infective process on a background of recent staphylococcal pneumonia. Notably her ESR was 5mm/1st hour and WCC were normal during this time. However, the clinical state was that of an infection and she was immediately treated with carbepenum as well as a systemic antifungals whilst awaiting cultures. Blood and sputum culture yielded extended-spectrum beta-lactamase (ESBL) organisms. As she was on ketoconazole, her cortisol reserve was insufficient to counteract the stress of severe infection and she received intravenous hydrocortisone with fluid resuscitation. As expected, her random blood cortisol done before steroid administration revealed a very low cortisol level of 151 nmol/L. Therefore, diagnostic tests had to be postponed at this stage as she was not fit enough for invasive investigations.

Following recovery from the infection, the patient underwent another CT scan of the chest to re-evaluate the lung lesions. This revealed resolution of almost all the cavitatory lesions and consolidation. Interestingly, the small area of consolidation in the right lower lobe remained the same. CT scan of abdomen and pelvis revealed bilateral nodular hyperplasia of the adrenals as well as a lesion

in the liver, which avidly enhanced with contrast. This was later confirmed to be a haemangioma by ultrasound assessment. Bronchoscopy did not reveal any endobronchial lesions. Octreotide scintigraphy or FDG-PET scan could not be performed due to non-availability.

A CT guided biopsy of her right lung nodule was performed and the histopathology revealed a tumour composed of nests of small cells with hyperchromatic nuclei having finely stippled chromatin. The mitotic count was low (2 per 10 hpf). Small, eosinophilic nucleoli were present staining strongly for ACTH, CD56, chromogranin and synaptophysin (figure 3).

These histological features are shared by SCLC as well as bronchial carcinoids. Differentiation of these 2 lesions can be done using the Ki-67 proliferation index, which would reveal a very low index for carcinoids whereas it would be a very high index for SCLC (figure 4).

Following the histological diagnosis of bronchial carcinoid, the patient underwent right lower lobectomy and she tolerated the procedure well. The resected specimen contained a 2.2 × 2.2 cm size bronchial carcinoid, which was reconfirmed with histology. Following thoracotomy and resection of her lung lesion, the plasma cortisol decreased significantly (post op 25nmol/L) and she remains well on maintenance dose of steroids. When reviewed in clinic 3 months after surgery, she was symptomatically well, with good lung function.

Discussion

Bronchial carcinoid, which is a low to moderate grade malignancy, typically has a long history and slow onset of symptoms (1-84 months, median 23.6). Due to this slow progressive nature of this tumour, the classical Cushingoid features are usually present by the time they present with clinical symptoms attributable to lung disease (3). Our patient had symptoms of cortisol excess for at least 12 months prior to presentation. As in most cases, the tumour by itself did not give rise to respiratory symptoms or signs, but secondary to infections of the lung.

The investigative process and management of a patient with CS is very challenging. The hypercortisolae mia leads to hyperglycemia, fluid retention, hypertension, severe infections, electrolyte abnormalities and many other problems that undoubtedly hinder the investigative process. Additionally, these patients cannot mount an adequate cortisol response (even though they have very high basal levels of cortisol) in the event of stress such as sepsis or surgery. Therefore, these patients are always at risk of adrenal crisis, especially when they are on adrenolytic drugs such as ketoconazole, as in this patient. Adrenal insufficiency occurs insidiously and has very subtle features such as better control of blood sugar and blood pressure in a previously uncontrolled patient or reduction in drug doses to achieve control. Thus, daily bedside assessment for these features is mandatory in addition to testing for cortisol levels to prevent an adrenal crisis. This case also highlights the immunocompromised nature of this disease process and the need for extra vigilance in identifying and treating them with steroids appropriately. Our patient presented with a severe atypical pneumonia and continued to have recurrent infections during the investigative process. She also developed urinary sepsis and infection at the catheter site after IPSS. In all these infections, her CRP and ESR did not increase and if the desired clinical vigilance was not advocated, these infections would have not been picked up until in a very advanced state.

Confirmatory investigations for suspected CS in the presence of severe sepsis and critical illness may lead to falsely elevated cortisol levels. Thus, the workup and evaluation for possible hypercortisolism should not be performed while patients are under stress.

Differentiating Cushing disease from an ectopic source of ACTH can be difficult. Generally, these patients
with ectopic secretion of ACTH have higher ACTH levels. They fail to suppress cortisol secretion for high doses of dexamethasone (8mg) and their pituitary adrenal responses to CRH stimulation is also absent (5, 6). However, 20–40% of patients with ectopic ACTH demonstrate cortisol suppression on high dose dexamethasone and 10–15% responds to CRH stimulation (6). Pituitary imaging may unmask incidental lesions and pose difficulties in the diagnosis. It is reported that, 10–20% of endocrinologically normal people have pituitary lesions of no clinical significance on pituitary imaging (7). Pituitary imaging can also lead to false negative results especially in the case of micro adenomas where dynamic imaging with contrast is not used. Modern MRI scanning has been reported to have only 70–80% sensitivities in the detection of micro adenomas (8).

The most valuable investigation for differentiating between pituitary and ectopic sources is the inferior petrosal venous sinus sampling (IPSS), which is considered as the gold standard. A baseline ACTH gradient between the inferior and the peripheral petrosal sinuses >2, and after stimulation with CRH/desmopressin >3, would indicate a pituitary source of ACTH secretion (9, 10). This is an invasive procedure, which need expert skills and may be difficult in a critically ill patients.

Once it is confirmed that the ACTH is from an ectopic source, the localization of the source of ectopic ACTH can be even more difficult, especially if standard imaging is negative. It is also important to consider the possibility of infections and unrelated benign incidental lesions, which may mislead the clinician if not interpreted in their true context. In our patient, the CT scan of the chest showed bilateral cavitatory lesions and the peripheral lung nodule. These findings along with the enhancing lesion in the liver could easily have been misdiagnosed as advanced malignancy. The index lesion in the lung was only made prominent after resolution of the florid inflammatory changes and in this situation, patience was the key to the diagnosis.

Confirmation of ectopic ACTH production requires demonstration of immunostaining positivity for ACTH in the resected tumour. Thereafter, the use of ki-67 marker is the key factor in differentiating SCLC from carcinoid tumour, as both these are entities are in a spectrum of neuroendocrine tumours.

Management of patients with ectopic ACTH requires control of the hypercortisolaemia as soon as the diagnosis is established (11). Ketoconazole and metyrapone have reasonable amount of evidence for their efficacy and safety (12, 13). Patients with identifiable sources of ectopic ACTH should have the tumours resected and surgery can offer a cure in more than 80% of bronchial carcinoids (12). Even with modern techniques, in as many as 12% of patients, the source of ACTH may not be found (11). Such cases with “occult” ACTH-secreting tumours remain a challenge and may need repeated investigations for many years. In such cases, bilateral adrenalectomy is the next best therapeutic option, but with the need for lifelong steroid replacement (14).

Conclusion

Ectopic ACTH secreting tumours present some of the most challenging differential diagnoses in endocrinology and require careful clinical, biochemical, radiological, and pathological investigation. Due vigilance for sepsis, adrenal insufficiency and other complications of high cortisol is needed and close liaison between the endocrinologist, endocrine surgeon, chemical pathologist, and radiologist in the management of these patients is the key for a successful outcome.
